Abstract

Recently, Mike and Farmer have constructed a very powerful and realistic behavioral model to mimic the dynamic process of stock price formation based on the empirical regularities of order placement and cancelation in a purely order-driven market, which can successfully reproduce the whole distribution of returns, not only the well-known power-law tails, together with several other important stylized facts. There are three key ingredients in the Mike-Farmer (MF) model: the long memory of order signs characterized by the Hurst index H_s , the distribution of relative order prices x in reference to the same best price described by a Student distribution (or Tsallis' q -Gaussian), and the dynamics of order cancelation. They showed that different values of the Hurst index H_s and the freedom degree α_x of the Student distribution can always produce power-law tails in the return distribution $f(r)$ with different tail exponent α_r . In this paper, we study the origin of the power-law tails of the return distribution $f(r)$ in the MF model, based on extensive simulations with different combinations of the left part $f_L(x)$ for $x < 0$ and the right part $f_R(x)$ for $x > 0$ of $f(x)$. We find that power-law tails appear only when $f_L(x)$ has a power-law tail, no matter $f_R(x)$ has a power-law tail or not. In addition, we find that the distributions of returns in the MF model at different timescales can be well modeled by the Student distributions, whose tail exponents are close to the well-known cubic law and increase with the timescale.

Key words: Econophysics; Mike-Farmer model; Power-law tail; q -Gaussian; Order-driven market

1 Introduction

Many stylized facts have been unveiled in different stock markets [1, 2, 3]. Understanding the underlying regularities causing stylized facts are crucial in stock market modeling. Three different families of market models exist aiming at reproducing the main stylized facts. The first family is the dynamic models, such as the multifractal model of asset returns [4], which was later extended in several publications [5, 6, 7, 8], and the multifractal random walks [9, 10, 11]. The second family is the agent-based models (or multi-agent models), in which agents buy or sell shares according to some rules and the price variations are determined by the imbalance of demand and supply. There are different types of agent-based models, such as percolation models [12, 13, 14, 15, 16, 17], Ising models [18, 19, 20, 21, 22, 23], minority games [24, 25, 26, 27, 28, 29, 30, 31], and others [32]. The minority games are among the most important agent-based models and thus many variants have been proposed. The third family is the order-driven models, where researchers attempt to simulate the dynamics of order books. The price in order-driven models changes based on the continuous double auction (CDA) mechanism [33, 34, 35]. A nice review of order-driven models was recently given by Slanina [36]. We can think of the agent-based models and the order-driven models as microscopic models for quote-driven markets and order-driven markets, respectively.

Recently, Mike and Farmer have constructed a very powerful and realistic behavioral model to mimic the dynamic process of stock price formation [37], which belongs to the third family. We call it *Mike-Farmer model*, or MF model for short. It seems undoubtable to us that the MF model is a milestone in the modeling of order-driven markets, which will prove to introduce an important improvement in asset derivative pricing and risk management. Having said this, we stress that the MF model is still very simple as mentioned already by Mike and Farmer [37] and there are still a lot of open problems to be addressed. Indeed, the MF model provides a nice platform to unravel the origin of stylized facts of stocks in order-driven markets. The essential advantage of the MF model is that it is constructed based on the empirical regularities of order placement and cancelation in a purely order-driven market, which can successfully reproduce the whole distribution of returns, not only the well-known power-law tails, together with several other important stylized facts. There are three key ingredients in the MF model: the long memory of order signs characterized by the Hurst index H_s , the distribution of relative order prices x in reference to the same best price described by a Student distribution, and the dynamics of order cancelation.

Through extensive simulations, Mike and Farmer found that different values of the

Hurst index H_s and the freedom degree α_x of the Student distribution can always produce power-law tails in the return distribution $f(r)$ with different tail exponent α_r . Specifically, they found that α_r increases almost linearly with α_x for fixed H_s and decreases approximately linearly with H_s for fixed α_x . Our simulations of the MF model with different values of α_x (ranging from 0.9 to 1.9 with a step of 0.1) and H_s (ranging from 0.1 to 0.9 with a step of 0.1) confirm this finding. Speaking differently we have simulated 9×11 versions of the MF model. For each version, four million simulation steps are conducted after removing the initial transient data and we obtain about one million data points of trade-by-trade returns. We find that the dependence of α_r upon H_s and α_x can be modeled using the following formula:

$$\alpha_r = 0.61 + 2.05\alpha_x - 0.11H_s - 0.34H_s\alpha_x. \quad (1)$$

These observations can be explained as follows. With the increase of H_s , the memory of order signs becomes stronger and more orders of the same direction (buy or sell) are placed successively. This results in more large price fluctuations and the decay of $f(r)$ becomes slower. Hence the tail exponent α_r decreases. On the other hand, if α_x is small, more passive orders with $x < 0$ are placed deep inside the order book and the standing volumes close to the best ask or bid price are relatively small. Speaking differently, the depth of the order book is low and the liquidity is low. Also, there are more aggressive orders with $x > 0$ placed resulting in more market orders. Both effects lead to more large price fluctuations and slower decay of the return distribution.

Although both the strength of the long memory of order signs and the tail exponent of relative order prices have significant influence on the distribution of returns, it is unclear what causes the power-law tails in the MF model. In this paper, we will address this question based on extensive simulations with different combinations of the left part $f_L(x)$ for $x < 0$ and the right part $f_R(x)$ for $x > 0$ of $f(x)$. We find that power-law tails appear only when $f_L(x)$ has a power-law tail, no matter $f_R(x)$ has a power-law tail or not. Moreover, we find that the return distributions in the MF model at different timescales can be well modeled by the Student (or Tsallis' q -Gaussian) distributions, whose tail exponents are close to the well-known cubic law and increase with the timescale.

2 Description of the Mike-Farmer model

In purely order-driven markets, the main trading mechanism is the continuous double auction. Passive traders are patient and place effective limit orders that are stored in the order book waiting for execution, while aggressive traders are impatient and submit effective market orders that are executed immediately. Consider a limit order placed at event time t whose logarithmic price is $\pi(t)$. Denote $\pi_a(t-1)$ and $\pi_b(t-1)$ the logarithms of best ask and bid prices right before t . A buy limit

order with $\pi(t) \geq \pi_a(t-1)$ or a sell limit order with $\pi(t) \leq \pi_b(t-1)$ is classified as an effective market order. Speaking differently, orders with the relative prices $x(t)$ less than the preceding spreads $S(t-1) = \pi_a(t-1) - \pi_b(t-1)$ are effective limit orders, while orders with $x(t) \geq S(t-1)$ are effective market orders¹. Orders waiting on the limit order book are either satisfied by future effective market orders or canceled. Therefore, the continuous double auction can be simulated if one knows the regularities governing the dynamic processes of order placement and cancelation. Most order-driven models also follow this line. However, to the best of our knowledge, the MF model is the only one that uses empirical regularities of order placement and cancelation extracted from real stock data. This is the reason why the MF model can reproduce the cubic law of return distribution without tuning any model parameters. Actually, the MF model does not introduce any artificial tunable model parameters at all. All parameters in the MF model are determined empirically and have clear financial meanings. The regularities of order placement and cancelation may be different for different stock markets. The MF model can be easily modified for other markets.

When placing an order, the trader needs to determine its sign (“+1” for buys and “−1” for sells), size and price (or the relative price x). In the MF model, all orders are assumed to have identical size. The signs of successive orders have strong memory, which can be characterized by a rather large Hurst index H_s close to 0.8 or even larger [37, 38]. This finding is conclusive without any controversy. In contrast, the distribution of relative prices seems different in different markets. Zovko and Farmer studied the unconditional distribution of relative limit prices defined as the distance from the same best prices for orders placed inside the limit-order book [39]. They merged the data from 50 stocks traded on the London Stock Exchange (August 1, 1998 to April 31, 2000) and found that the distribution decays roughly as a power law with the tail exponent $\alpha = 1.5$ for both buy and sell orders. Bouchaud *et al.* analyzed the order books of three liquid stocks on the Paris Bourse (February 2001) and found that the relative price of new orders placed inside the book follows a power-law distribution with the tail exponent $\alpha = 0.6$ [40]. Potters and Bouchaud investigated the relative limit price distributions for inside-the-book orders of three Nasdaq stocks (June 1 to July 15, 2002) and found that the distributions exhibit power-law tails with an exponent $\alpha = 1$ [41]. Maskawa analyzed 13 rebuild order books of Stock Exchange Electronic Trading Service from July to December in 2004 on the London Stock Exchange and found that the limit prices for all orders inside the book are broadly distributed with a power-law tail whose exponent is $\alpha = 1.5$ [42], which is consistent with the results of Zovko and Farmer [39]. He also presented the distribution in the negative part for more aggressive order outside the book and found that the negative part decays much faster than the positive part. Mike and Farmer focused on the stock named AZN and tested on 24 other stocks listed on the London Stock Exchange (LSE) [37]. They found that

¹ The relative price $x(t)$ is defined as $\pi(t) - \pi_b(t-1)$ for buy orders and $\pi_a(t-1) - \pi(t)$ for sell orders.

the distribution of relative logarithmic prices can be fitted by a Student distribution with $\alpha = 1.0 - 1.65$ degrees of freedom and the distribution is independent of bid-ask spread at least over a restricted range for both buy and sell orders. Gu, Chen and Zhou analyzed 23 Chinese stocks traded on the Shenzhen Stock Exchange (SZSE) and found that the distribution of relative prices is asymmetric [43]. They showed that the distribution has power laws with the exponents greater than 1 and lower than 2.

There are also efforts to seek for factors influencing order placement. Using 15 stocks on the Swiss Stock Exchange, Rinaldo found that both bid-ask spread and volatility negatively relate to order aggressiveness [44]. Lillo analyzed the origin of power-law distribution of limit order prices considering the order placement as an utility maximization problem considering three factors: time horizon, utility function and volatility [45]. He found that the heterogeneity in time horizon is the proximate cause of the asymptotic power-law distribution, while heterogeneity in volatility is hardly connected with the origin of power-law distribution. Mike and Farmer found that the distribution $f(x)$ of LSE stocks is independent of the bid-ask spread [37], which was confirmed by Gu, Chen and Zhou using SZSE stocks [43].

In a zero intelligence model [34, 35], order cancelation is assumed to be a Poisson process. Alternatively, Mike and Farmer found that the conditional probability of canceling an order i at time t is influenced by at least three factors [37]: the ratio y_i of current relative price of an order to its original relative price when it is placed, the number n_{tot} of orders in the order book, and the order book imbalance n_{imb} that is defined as the ratio of the number of buy (or sell) orders to n_{tot} . By assuming that y_i , n_{tot} and n_{imb} are independent, the conditional probability of cancelation per order has the following form:

$$P(C_i|y_i, n_{\text{tot}}, n_{\text{imb}}) = A(1 - e^{-y_i})(n_{\text{imb}} + B)/n_{\text{tot}}, \quad (2)$$

where the parameters A and B are determined empirically using real data of individual stocks [37].

Now we can describe the MF model as follows. We stress that the sizes of orders are set to unity. In each round of the simulation, we simulate 2×10^5 steps and the first 2000 data points are discarded from the ensuing analysis. We repeat this process 20 times, which results in four million orders and about one million transactions. In each round, we generate two arrays of the relative prices $x(t)$ and the order signs $s(t)$. The sign array of the orders is generated from a fractional Brownian motion with Hurst index H_s and the relative price x is taken from a Student distribution with scale σ_x and α_x degrees of freedom. At each simulation step or event time t , an order is generated, which is characterized by $x(t)$ and $s(t)$. When $x(t) \geq S(t-1)$, the order is executed and a buy limit order (if $s(t) < 0$) or a sell limit order (if $s(t) > 0$) at the best bid or ask price is removed from the order book. When $x(t) < S(t-1)$, the order is stored in the order book at the price level

$T \text{int}[\pi(t)/T]$, where T is the tick size, $\text{int}[z]$ is the largest integer smaller than z , and $\pi(t) = x(t) + \pi_b(t-1)$ for buy orders or $\pi(t) = \pi_a(t-1) - x(t)$ for sell orders. We then calculate the values of $P(C_i|y_i, n_{\text{tot}}, n_{\text{imb}})$ for all orders waiting in the order book. A random number $p(t)$ is drawn from a uniform distribution defined on the interval $[0, 1]$. All orders with $P(C_i|y_i, n_{\text{tot}}, n_{\text{imb}}) \leq p(t)$ are canceled from the order book. The returns between successive trades are used in this work. We note that the results presented in [37] are successfully reproduced in our simulations.

3 The origin of power-law tail of returns

3.1 Methodology

Mike and Farmer have shown that the power-law tails in the return distribution $f(r)$ become heavier if the long memory in the order signs is stronger [37]. We notice that the power-law tails do not vanish even when $H_s = 0.5$. In other words, long memory in the order signs cannot explain the emergence of power-law tails of returns. Therefore, we turn to investigate the influence of $f(x)$ on $f(r)$. According to the setting of the MF model, the shape of $f(x)$ for $x > S$ does not impact the shape of $f(r)$, since those orders are effective market orders that always remove one unit of shares from the opposite side of the order book, despite of the true prices of the incoming effective market orders. We thus speculate that the right part of $f(x)$, denoted as $f_R(x)$, has much weaker influence than the left part $f_L(x)$. In our simulations, the tick size is $T = 3 \times 10^{-4}$ and three model parameters are fixed according to [37]: $H_s = 0.8$, $A = 1.12$, and $B = 0.2$.

In order to unveil the effect of the two parts of $f(x)$ on the tail behavior of $f(r)$, we adopt different formulae for $f(x)$. In general, we can write the following

$$f(x) = \begin{cases} f_L(x), & x \leq 0 \\ f_R(x), & x \geq 0 \end{cases}. \quad (3)$$

Obviously, when $x = 0$, we require that

$$f_L(0) = f_R(0). \quad (4)$$

In the MF model, $f(x) = f_L(x) = f_R(x)$. In this section, we will use different functional forms for $f_L(x)$ and $f_R(x)$.

The first class is the Student density [46] or Tsallis' q -Gaussian [47], whose density

is

$$f_{qG}(x|\alpha_x, L) = \frac{\sqrt{L}\alpha_x^{\frac{\alpha_x}{2}}}{B\left(\frac{1}{2}, \frac{\alpha_x}{2}\right)} (\alpha_x + Lx^2)^{-\frac{\alpha_x+1}{2}}, \quad (5)$$

where α_x is the degrees of freedom parameter (or tail exponent), L is the scale parameter, and $B(a, b)$ is the Beta function, that is, $B(a, b) = \Gamma(a) \Gamma(b) / \Gamma(a+b)$ with $\Gamma(\cdot)$ being the gamma function. The second class is the Laplace distribution or double exponential distribution, whose density is

$$f_{DE}(x|\lambda) = \frac{\lambda}{2} e^{-\lambda|x|}, \quad (6)$$

and the third class is the normal distribution, whose density is

$$f_G(x|\sigma) = \frac{1}{\sqrt{2\pi}\sigma} e^{-x^2/2\sigma^2}, \quad (7)$$

According to the symmetry of the distribution of x in the MF model [37], the mean of x is fixed to null in all these distributions.

In the model specification, we choose $f_L(x)$ and $f_R(x)$ from f_{qG} , f_{DE} and f_G , respectively. The constraint (4) can be specified for different combination of $f_L(x)$ and $f_R(x)$ as follows. When the two parts of $f(x)$ are f_{qG} and f_{DE} , we have

$$2\sqrt{L/\alpha_x} = \lambda B(1/2, \alpha_x/2). \quad (8)$$

When the two parts of $f(x)$ are f_{qG} and f_G , we have

$$B(1/2, \alpha_x/2) = \sigma \sqrt{2\pi L/\alpha_x}. \quad (9)$$

When the two parts of $f(x)$ are f_{DE} and f_G , we have

$$\lambda^2 \sigma^2 = 2/\pi, \quad (10)$$

which is equivalent to the combination of Eq. (8) and Eq. (9).

We fix $\sigma_x = 0.0024$ in all the simulations so that the simulated sample of x is comparable to real data [37]. The values of L in Eq. (5) are calculated as follows:

$$L = \alpha_x / [(1 + \alpha_x) \sigma_x^2]. \quad (11)$$

The values of λ and σ are determined respectively according to Eq. (8) and Eq. (9) for different values of α_x . We investigate different combinations of $f_L(x)$ and $f_R(x)$ according to if they have a power-law tail. The case that both parts have a power-law tail has been studied by Mike and Farmer [37], as discussed in Section 1. Therefore, we are left with three cases: (1) There are no power-law tails in $f(x)$; (2) The right part of $f(x)$ has a power-law tail with $f_R(x) = f_{qG}(x|\alpha_x, L)$; and (3) The left part of $f(x)$ has a power-law tail with $f_L(x) = f_{qG}(x|\alpha_x, L)$. We shall investigate these

three cases in the rest of this section.

3.2 Case 1: There are no power-law tails in $f(x)$

In this case, there are no power-law tails in $f(x)$ and we have four combinations for $f_L(x)$ and $f_R(x)$ that are $\{f_{DE}(x|\lambda), f_G(x|\sigma)\}$, $\{f_{DE}(x|\lambda), f_{DE}(x|\lambda)\}$, $\{f_G(x|\sigma), f_{DE}(x|\lambda)\}$, and $\{f_G(x|\sigma), f_G(x|\sigma)\}$. For each combination, we investigate five different values of α_x from 1.1 to 1.9 with a step of 0.2. For each value of α_x , our simulations are conducted for 20 repeated rounds. In each round, 2×10^5 incoming orders are generated, driving the trading system evolve, and the first 2000 orders are excluded from analysis. The complementary cumulative distribution can be determined for each α_x in every combination. We show the tails of $F(|r|)$, which is the complementary cumulative probability distribution of $|r|$, since the return distributions are almost symmetric for positive and negative returns.

The resultant 20 empirical distributions of the trade-by-trade absolute returns $|r|$ for each combination are given in Fig. 1(a). It is evident that there is no power-law tails observed in the distributions. For each combination, the distribution $F(|r|)$ decays faster for larger α_x . We also find that there are more large returns for the two combinations where $f_L = \{f_{DE}(x|\lambda)\}$. This is explained by the two facts that $f_L(x)$ has stronger impact on $F(|r|)$ or equivalently $f(r)$ and that a Laplace distribution has heavier tails than a Gaussian. Fig. 1(b) presents the distributions of the standardized returns $g = (r - \mu_r)/\sigma_r$, where $\mu_r (\approx 0)$ and σ_r are respectively the mean and the standard deviation of r . It is interesting to observe that the five distributions collapse onto a single curve for all four combinations.

Fig. 1. (Color online) Resultant distribution of the trade-by-trade absolute returns $|r|$ (a) and the corresponding standardized returns $|g|$ (b) when the relative price distribution $f(x)$ has no power-law tails. Each cluster of curves corresponds to a combination of $f_L(x)$ and $f_R(x)$. The clusters have been shifted vertically for clarification. The associated combination $\{f_L(x), f_R(x)\}$ from top to bottom is $\{f_{DE}(x|\lambda), f_G(x|\sigma)\}$, $\{f_{DE}(x|\lambda), f_{DE}(x|\lambda)\}$, $\{f_G(x|\sigma), f_{DE}(x|\lambda)\}$, and $\{f_G(x|\sigma), f_G(x|\sigma)\}$, where λ and σ are determined respectively according to Eq. (8) and Eq. (9) for different values of α_x .

3.3 Case 2: The right part of $f(x)$ has a power-law tail with $f_R(x) = f_{qG}(x|\alpha_x, L)$

In this case, the right part of $f(x)$ has a power-law tail with $f_R(x) = f_{qG}(x|\alpha_x, L)$ and we have two combinations for $f_L(x)$ and $f_R(x)$: $\{f_{DE}(x|\lambda), f_{qG}(x|\alpha_x, L)\}$ and $\{f_G(x|\sigma), f_{qG}(x|\alpha_x, L)\}$. The simulation procedure is the same as in Section 3.2. The resultant 10 empirical distributions of the trade-by-trade absolute returns $|r|$ for each combination are given in Fig. 2(a). Again, no power-law tails are observed in these distributions. For each combination, the distribution $F(|r|)$ decays faster for larger α_x . We also find that there are more large returns for the combination where $f_L = \{f_{DE}(x|\lambda)\}$. The same explanation applies. Fig. 2(b) presents the distributions of the normalized returns $|g|$ and the five distributions for each combination collapse remarkably onto a single curve.

Fig. 2. (Color online) Resultant distribution of the trade-by-trade absolute returns $|r|$ (a) and the corresponding normalized returns $|g|$ (b) when the right part of $f(x)$ has a power-law tail, that is, $f_R(x) = f_{qG}(x|\alpha_x, L)$. The upper cluster of curves corresponds to $f_L(x) = f_{DE}(x|\lambda)$ and the lower cluster corresponds to $f_L(x) = f_G(x|\sigma)$, where λ and σ are determined respectively according to Eq. (8) and Eq. (9) for different values of α_x . The lower cluster has been shifted downwards for clarification.

3.4 Case 3: The left part of $f(x)$ has a power-law tail with $f_L(x) = f_{qG}(x|\alpha_x, L)$

In this case, the left part of $f(x)$ has a power-law tail with $f_L(x) = f_{qG}(x|\alpha_x, L)$ and we have two combinations for $f_L(x)$ and $f_R(x)$, which are $\{f_{qG}(x|\alpha_x, L), f_{DE}(x|\lambda)\}$ and $\{f_{qG}(x|\alpha_x, L), f_G(x|\sigma)\}$. The simulation procedure is the same as in Section 3.2. The resultant empirical distributions of the trade-by-trade absolute returns $|r|$ for each combination are depicted in Fig. 3(a) and (b), respectively. Nice power-law tails are observed in all the distributions. For each combination, the tail exponent α_r increases with α_x . Comparing the distributions in the two plots, no significant difference can be identified in the return distributions with the same value of α_x . In other words, the shape of $F(|r|)$ or equivalently $f(r)$ is fully determined by $f_R(x) = f_{qG}(x|\alpha_x, L)$. It is not out of expectation that there is no scaling in the distributions of the normalized returns, $F(|g|)$, and we thus do not show them here.

Fig. 3. (Color online) Resultant distribution of the trade-by-trade absolute returns $|r|$ when the left part of $f(x)$ has a power-law tail, that is, $f_L(x) = f_{qG}(x|\alpha_x, L)$. The right part of $f(x)$ is $f_R(x) = f_{DE}(x|\lambda)$ in (a) and $f_R(x) = f_G(x|\sigma)$ in (b), where λ and σ are determined respectively according to Eq. (8) and Eq. (9) for different values of α_x .

In summary, our simulations confirms that the return distribution is mainly determined by the distribution of the relative prices of incoming orders placed within the order book with $x \leq 0$. Heavier tail in $f_L(x)$ will result in heavier tails in $f(r)$. Only when $f_L(x)$ has a power-law tail, $f(r)$ will have power-law tails.

4 The return distributions at different timescales

We now investigate the return distributions at different timescales for the MF model with the parameters being extracted from real data [37]. Specifically, the values of model parameters used in this section are the following: $\alpha_x = 1.3$, $\sigma_x = 0.0024$, $H_s = 0.8$, $A = 1.12$, and $B = 0.2$. We stress that x follows the Student distribution in the standard MF model. The simulation procedure is the same as described in the previous section. We consider the normalized returns rather than the returns *per se* for convenience.

We adopt the mid-price of the best bid $\pi_b(t)$ and best ask $\pi_a(t)$ as the logarithmic price at time t after a transaction occurs:

$$I(t) = \frac{\pi_b(t) + \pi_a(t)}{2}, \quad (12)$$

where t is the event time corresponding to single trades. The event-time return after Δt trades is then defined as the logarithmic price change:

$$r_{\Delta t}(t) = I(t) - I(t - \Delta t). \quad (13)$$

Here we deal with the standardized returns

$$g_{\Delta t}(t) = [r_{\Delta t}(t) - \mu_{\Delta t}]/\sigma_{\Delta t}, \quad (14)$$

where $\mu_{\Delta t}$ and $\sigma_{\Delta t}$ are respectively the mean and the standard deviation of returns $r_{\Delta t}$. For simplicity, we drop the subscript $r_{\Delta t}$ below.

4.1 Probability distributions of trade-by-trade returns

We first focus on $\Delta t = 1$. The empirical probability density function $f(g)$ is estimated, as shown in Fig. 4(a). We find that $f(g)$ can be well modeled by a Student density. Nonlinear least-squares regression gives $\alpha_r = 2.9$ and $L = 3.3$. The fitted curve is drawn on the left panel. According to Fig. 4(a), the Student density fits nicely the tails of the empirical density $f(g)$. The fitted model deviates from the empirical density remarkably for small values of $|g|$. If we amplify the central part for small $|g|$ with finer binning, the shape of $f(g)$ looks like a Mexican hat. This is the very character of return distributions of individual stocks caused by the discreteness of price changes in units of tick size. This intriguing structure was reported for common stocks in the US market [48] and in the Chinese market [43].

Fig. 4. Empirical probability density function of the normalized trade-by-trade returns. Panel (a): Empirical probability density function $f(g)$ of the normalized returns g . The solid line is the Student density with $\alpha_r = 2.9$ and $L = 3.3$. Panel (b): Empirical cumulative distributions $F(|g|)$ for positive and negative normalized returns g . The solid lines are the least squares fits of power laws to the data with $\alpha_r^+ = 2.87 \pm 0.02$ for the positive tail and $\alpha_r^- = 3.06 \pm 0.03$ for the negative tail.

For large values of $|g|$, the Student density function $f(g)$ approaches power-law decay in the tails:

$$f(g) \sim \begin{cases} (-g)^{-(\alpha_r^-+1)} & \text{for } g < 0 \\ (+g)^{-(\alpha_r^++1)} & \text{for } g > 0 \end{cases}. \quad (15)$$

The empirical cumulative distributions $F(|g|)$ of positive g and negative g are illustrated in Fig. 4(b). Both positive and negative tails decay in a power-law form with $\alpha_r^+ = 2.87 \pm 0.02$ and $\alpha_r^- = 3.06 \pm 0.03$, which are in line with the tail exponent α_r estimated from the Student model. These results indicate that the standardized returns obey the (inverse) cubic law.

4.2 Probability distributions of trade-aggregated returns

We now turn to investigate the distributions of the standardized trade-aggregated returns $g_{\Delta t}$, where Δt spans several trades. By varying the value of Δt , we are able to compare the PDF's at different timescales. Specifically, we compare the PDFs for $\Delta t = 2, 4, 8$ and 16 trades with that for $\Delta t = 1$ trade. As listed in the second column of Table 1, the kurtosis of each PDF is significantly greater than that of the Gaussian distribution whose kurtosis is 3, indicating a much slower decay in the tails. In addition, the kurtosis decreases with respect to the scale Δt . Very similar leptokurtic behavior exists in real stock markets [1].

Table 1

Characteristic parameters for trade-aggregated returns.

Δt	Kurtosis	q -Gaussian		Positive tail		Negative tail	
		L	α_r	Scaling range	α_r^+	Scaling range	α_r^-
1	19.68	3.3	2.9	$1.5 \leq g \leq 50.1$	2.87 ± 0.02	$1.5 \leq -g \leq 39.8$	3.06 ± 0.03
2	19.52	3.1	3.0	$1.5 \leq g \leq 36.3$	2.90 ± 0.02	$1.5 \leq -g \leq 30.2$	3.15 ± 0.04
4	17.06	3.2	3.1	$1.5 \leq g \leq 27.7$	2.94 ± 0.03	$1.7 \leq -g \leq 22.9$	3.24 ± 0.04
8	13.91	2.9	3.2	$1.7 \leq g \leq 15.8$	3.07 ± 0.04	$1.7 \leq -g \leq 15.9$	3.42 ± 0.05
16	10.72	2.5	3.5	$1.7 \leq g \leq 12.1$	3.39 ± 0.05	$1.9 \leq -g \leq 7.6$	3.77 ± 0.07

Fig. 5. (Color online) Empirical distributions of aggregated returns at different time scales $\Delta t = 1, 2, 4, 8$ and 16 . Panel (a): Empirical densities $f(g)$ of the aggregated returns. Panel (b): Empirical cumulative distributions $F(|g|)$ for positive (upper cluster of curves) and negative (lower cluster of curves) returns g .

The empirical $f(g)$ functions for different time scales Δt are illustrated in Fig. 5(a). We represent the distribution of one-trade returns for comparison. It is evident that the tail is heavier with the decrease of Δt . This phenomenon can also be characterized by the kurtosis of the distributions. We also notice that the PDF for $\Delta t = 16$ decays slower than exponential. We have fitted the five curves using the Student density model (5) and the estimated parameters L and α_r are listed in Table 1. In

Fig. 5(b), we study the tail distributions of the normalized returns g . It is observed that both positive and negative tails decay in power-law forms. We have estimated the tail exponents, which are also presented in Table 1. Note that the scaling range decreases with increasing Δt , which is also observed for two Korean indexes [49] and 23 individual Chinese stocks [43]. As expected, the tails that are characterized by their tail exponents α_r decay faster for larger Δt , which is consistent with the behavior of kurtosis.

The results obtained so far show that, the mock stock simulated from the MF model shares striking similarity in the price dynamics with the Chinese stocks [43]. However, there are also minor discrepancies. First, the tail exponents of the mock stock are less than that of the Chinese stocks with about 0.2. Second, the return distributions are slightly left-skewed while that of the Chinese stocks are slightly right-skewed. It is not clear if these discrepancies stem from the simplicity of the MF model or are just a reflection of the fact that the parameters of the MF model are not extracted from the Chinese stocks. The analysis presented here shows that the MF model is very powerful and universal.

5 Conclusion

In conclusion, we have studied the return distributions of mock stocks in the Mike-Farmer model based on extensive simulations. We found that the power-law tails of the return distribution $f(r)$ in the MF model are caused by the power-law tail in the left part $f_L(x)$ of the distribution of the relative prices of incoming orders, no matter the right part $f_R(x)$ has a power-law tail or not. In addition, we found that the distributions of returns in the MF model at different timescales in units of trades can be modeled by Student distributions, whose tail exponents are close to the well-known cubic law and increase with timescale. The behavior of return distributions is comparable to that of the real data.
